## Eigenvalue Decomposition

- For a square matrix $\mathbf{A} \in \mathbb{C}^{n \times n}$, there exists at least one $\lambda$ such that
$|A-\lambda I|=0$

$$
\mathbf{A} \mathbf{x}=\lambda \mathbf{x} \quad \Rightarrow \quad(\mathbf{A}-\lambda \mathbf{I}) \mathbf{x}=\mathbf{0}
$$

- Putting the eigenvectors $\mathbf{x}_{j}$ as columns in a matrix $\mathbf{X}$, and the eigenvalues $\lambda_{j}$ on the diagonal of a diagonal matrix $\boldsymbol{\Lambda}$, we get

- A matrix is non-defective or diagonalizable if there exist $n$ linearly independent eigenvectors, i.e., if the matrix $\mathbf{X}$ is invertible:

leading to the eigen-decomposition of the matrix

$$
\mathbf{A}=\mathbf{X} \boldsymbol{\wedge} \mathbf{X}^{-1}
$$

## Unitarily Diagonalizable Matrices

- A unitary or orthogonal matrix $\mathbf{U}$ has orthogonal colums each of which has unit $L_{2}$ norm:

$$
\mathbf{U}^{-1}=\mathbf{U}^{\star}
$$

Unitary is used for complex matrices and is more general than orthogonal, reserved for real matrices.
Recall that star denotes adjoint (conjugate transpose).

- Unitary matrices are important because they are always well-conditioned, $\kappa_{2}(\mathbf{U})=1$.
- A matrix is unitarily diagonalizable if there exist $n$ linearly independent orthogonal eigenvectors, $\mathbf{X} \equiv \mathbf{U}$,

$$
\longrightarrow \mathbf{A}=\mathbf{U} \mathbf{\Lambda} \mathbf{U}^{\star} .
$$

- Theorem: Hermitian matrices, $\mathbf{A}^{\star}=\mathbf{A}$, are unitarily diagonalizable
- and have real eigenvalues.

For real matrices we use the term symmetric.

## Non-diagonalizable Matrices

- For matrices that are not diagonalizable, one can use Jordan form factorizations, or, more relevant to numerical mathematics, the Schur factorization (decomposition):

$$
\mathbf{A}=\mathbf{U} \mathbf{T} \mathbf{U}^{\star}
$$

where $\mathbf{T}$ is upper-triangular (unlike Jordan form where only nonzeros are on super-diagonal).

- The eigenvalues are on the diagonal of $\mathbf{T}$, and in fact if $\mathbf{A}$ is unitarily diagonalizable then $\mathbf{T} \equiv \boldsymbol{\Lambda}$.
- The Schur decomposition is not unique but it is the best generalization of the eigenvalue (spectral) decomposition to general matrices.

## Singular Value Decomposition (SVD)

Every matrix has a singular value decomposition (SVD)

$$
\begin{aligned}
V^{-1} V^{\wedge} & V^{-1}=U^{p} \\
\mathbf{A} & =\mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^{\star}=\sum_{i=1}^{p} \sigma_{i} \mathbf{u}_{i} \mathbf{v}_{i}^{\star} \\
{[m \times n] } & =[m \times m][m \times n][n \times n],
\end{aligned}
$$

where $\mathbf{U}$ and $\mathbf{V}$ are unitary matrices whose columns are the left, $\mathbf{u}_{i}$, and the right, $\mathbf{v}_{i}$, singular vectors, and

$$
\boldsymbol{\Sigma}=\operatorname{Diag}\left\{\sigma_{1}, \sigma_{2}, \ldots, \sigma_{p}\right\}
$$

is a diagonal matrix with real positive diagonal entries called singular values of the matrix

and $p=\min (m, n)$ is the maximum possible rank of the matrix.

## Comparison to eigenvalue decomposition

- Recall the eigenvector decomposition for diagonalizable matrices

$$
\mathbf{A X}=\mathbf{X} \mathbf{\Lambda} .
$$

n

- The singular value decomposition can be written similarly to the eigenvector one

$$
\begin{aligned}
\mathbf{A} \mathbf{V} & =\mathbf{U} \mathbf{\Sigma} \\
\mathbf{A}^{\star} \mathbf{U} & =\mathbf{V} \mathbf{\Sigma}
\end{aligned}
$$

and they both diagonalize $\mathbf{A}$, but there are some important differences:
(1) The SVD exists for any matrix, not just diagonalizable ones.
(2) The SVD uses different vectors on the left and the right (different basis for the domain and image of the linear mapping represented by A).
(3) The SVD always uses orthonormal basis (unitary matrices), not just for unitarily diagonalizable matrices.

Relation to Eigenvalues

$$
\text { Cholodery } A^{\top} A_{x} x=A^{\top} b \quad \begin{aligned}
& \text { normal } \\
& \text { equations }
\end{aligned}
$$

- For Hermitian (symmetric) matrices, there is no fundamental difference between the SVD and eigenvalue decompositions (and also the Schur decomposition).
- The squared singular values arg eigenvalues of the normal matrix:

$$
\sigma_{i}(\mathbf{A})=\sqrt{\lambda_{i}\left(\mathbf{A A}^{\star}\right)}=\sqrt{\lambda_{i}\left(\mathbf{A}^{\star} \mathbf{A}\right)}
$$

since

$$
\left(\underline{\underline{\mathbf{A}^{\star} \mathbf{A}}=\left(\mathbf{V} \boldsymbol{\Sigma} \mathbf{U}^{\star}\right)\left(\mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^{\star}\right)=\underline{\mathbf{V}^{*} \Sigma \mathbf{V}^{\star}}}\right.
$$

- Similarly, the singular vectors are eigenvectors of $\mathbf{A}^{\star} \mathbf{A}$ or $\mathbf{A A}^{\star}$.

$$
\frac{A^{*} A \text { is SPD }}{\text { (thus diasuatitable) }}
$$

$$
\sum^{*}=\sum
$$

## Rank-Revealing Properties

- Assume the rank of the matrix is $r$, that is, the dimension of the range of $\mathbf{A}$ is $r$ and the dimension of the null-space of $\mathbf{A}$ is $n-r$ (recall the fundamental theorem of linear algebra).
- The SVD is a rank-revealing matrix factorization because only $r$ of the singular values are nonzero,

$$
\sigma_{r+1}=\cdots=\sigma_{p}=0
$$

- The left singular vectors $\left\{\mathbf{u}_{1}, \ldots, \mathbf{u}_{r}\right\}$ form an orthonormal basis for the range (column space, or image) of $\mathbf{A}$.
- The right singular vectors $\left\{\mathbf{v}_{r+1}, \ldots, \mathbf{v}_{n}\right\}$ form an orthonormal basis for the null-space (kernel) of $\mathbf{A}$.

## The matrix pseudo-inverse

## $A x=b$

- For square non-singular systems, $\mathbf{x}=\mathbf{A}^{-1} \mathbf{b}$. Can we generalize the matrix inverse to non-square or rank-deficient matrices?
- Yes: matrix pseudo-inverse (Moore-Penrose inverse):
where

$$
\operatorname{dagge} \overrightarrow{\mathbf{A}}^{\dagger}=\mathbf{V} \boldsymbol{\Sigma}^{\dagger} \mathbf{U}^{\star}
$$

$$
\begin{aligned}
& \text { Inverse): } \\
& A=V V_{-1}^{*}
\end{aligned}
$$

$$
A^{-1}=\left(V^{-1} \sum^{-1} U^{-1}\right.
$$

$$
\boldsymbol{\Sigma}^{\dagger}=\operatorname{Diag}\left\{\sigma_{1}^{-1}, \sigma_{2}^{-1}, \ldots, \sigma_{r}^{-1}, 0, \ldots, 0\right\} .=\left(V^{-1}\right)^{-1} \varepsilon^{-1} U^{-1}
$$

- In numerical computations very small singular values should be -1 considered to be zero (see homework).
- The least-squares solution to over- or under-determined linear systems $\mathbf{A x}=\mathbf{b}$ can be obtained from:
$A^{-1} b=V E^{-1} U^{*} b$

$$
\mathbf{x}=\mathbf{A}^{\dagger} \mathbf{b}
$$

## (3) Singular Value Decomposition

4. Principal Component Analysis (PCA)
(5) Conclusions

Sensitivity of Eigenvalues

- Now consider a perturbation of a diagonalizable matrix $\delta \mathbf{A}$ and see how perturbed the similar matrix becomes: assume $X$ fixed

$$
\begin{gathered}
\mathbf{X}^{-1}(\underline{\mathbf{A}+\delta \mathbf{A}) \mathbf{X}=\boldsymbol{\Lambda}+\delta \boldsymbol{\Lambda} \Rightarrow} \\
\delta \mathbf{\Lambda}=\mathbf{X}^{-1}(\delta \mathbf{A}) \mathbf{X} \Rightarrow \\
\|\delta \mathbf{\Lambda}\| \leq\left\|\mathbf{X}^{-1}\right\|\|\delta \mathbf{A}\|\|\mathbf{X}\|=\kappa(\mathbf{X})\|\delta \mathbf{A}\|
\end{gathered}
$$

- Conclusion: The conditioning of the eigenvalue problem is related to the conditioning of the matrix of eigenvectors.

## Conditioning of Eigenvalue problems

- If $\mathbf{X}$ is unitary then $\|\mathbf{X}\|_{2}=1$ (from now on we exclusively work with the 2-norm): Unitarily diagonalizable matrices are always perfectly conditioned!
- Warning: The absolute error in all eigenvalues is of the same order, meaning that the relative error will be very large for the smallest eigenvalues. $\quad \delta \lambda_{k} \approx 10^{-16 . \delta \lambda_{1} \leftarrow ~}$
- The conditioning number for computing eigenvectors is inversely proportional to the separation between the eigenvalues

$$
\kappa(\mathbf{x}, \mathbf{A})=\left(\min _{j}\left|\lambda-\lambda_{j}\right|\right)^{-1}
$$

## The need for iterative algorithms

- The eigenvalues are roots of the characteristic polynomial of $\mathbf{A}$, which is generally of order $n$.
- According to Abel's theorem, there is no closed-form (rational) solution for $n \geq 5$.

## All eigenvalue algorithms must be iterative!

- There is an important distinction between iterative methods to:
- Compute all eigenvalues (similarity transformations). These are based on dense-matrix factorizations such as the $Q R$ factorization, with total cost $O\left(n^{3}\right)$.
- Compute only one or a few eigenvalues, typically the smallest or the largest one (e.g., power method). These are similar to iterative methods for solving linear systems.

## Sparse Matrices

$A=X \cap X^{-1}$

$$
A^{2}=x n x^{-1} x n x^{-1}=x n^{2} x^{-1}
$$

- Recall that for a diagonalizable matrix

$$
\mathbf{A}^{n}=\mathbf{X} \boldsymbol{\Lambda}^{n} \mathbf{X}^{-1}
$$

and assume well-separated eigenvalues $\left|\lambda_{1}\right|>\left|\lambda_{2}\right| \geq\left|\lambda_{3}\right| \cdots\left|\lambda_{n}\right|$, and that the columns of $\mathbf{X}$ are normalized, $\psi_{X_{j}} \|=1$.

- For sparse matrices we sometimes only need to know a few of the eigenvalues/vectors, not all of them.
- Notably, knowing the eigenvector corresponding to the smallest and largest (in magnitude) eigenvalues is often most important (see Google Page Rank algorithm).

$$
\exp (A)=X \exp (N) X^{-1}
$$

## Iterative Method

$$
q_{0} \approx x_{1}
$$

- Any initial guess vector $\mathbf{q}_{0}$ can be represented in the linear basis formed by the eigenvectors

$$
\mathbf{q}_{0}=\mathbf{X a}
$$

- Recall iterative methods for linear systems: Multiply a vector with the matrix A many times:

$$
\begin{gathered}
\mathbf{q}_{k+1}=\mathbf{A} \mathbf{q}_{k} \\
\mathbf{q}_{n}=\mathbf{A}^{n} \mathbf{q}_{0}=\left(\mathbf{X} \Lambda^{n} \mathbf{X}^{-1}\right) \mathbf{X a}=\mathbf{X}\left(\boldsymbol{\Lambda}^{n} \mathbf{a}\right)\left[\begin{array}{c}
\text { converges }
\end{array}\left[\begin{array}{c}
\mathbf{a}_{1} \\
0 \\
\vdots \\
0
\end{array}\right]\right.
\end{gathered}
$$

## Power Method

- As $n \rightarrow \infty$, the eigenvalue of largest modulus $\lambda_{0}$ will dominate,

$$
\begin{aligned}
& \boldsymbol{\Lambda}^{n}=\lambda_{1}^{n} \operatorname{Diag}\left\{1,\left(\frac{\lambda_{2}}{\lambda_{1}}\right)^{n}, \ldots\right\} \rightarrow \operatorname{Diag}\left\{\lambda_{1}^{n}, \lambda_{2}{ }_{2}^{2}, \ldots, 0\right\}
\end{aligned}
$$

- Therefore the normalized iterates converge to the eigenvector:

$$
\tilde{\mathbf{q}}_{n}=\frac{\mathbf{q}_{n}}{\left\|\mathbf{q}_{n}\right\|}
$$

- The Rayleigh quotient converges to the eigenvalue:

$$
r_{A}\left(\mathbf{q}_{n}\right)=\frac{\mathbf{q}_{n}^{\star} \mathbf{A} \mathbf{q}_{n}}{\mathbf{q}_{n} \cdot \mathbf{q}_{n}}=\tilde{\mathbf{q}}_{n}^{\star} \mathbf{A} \tilde{\mathbf{q}}_{n} \rightarrow \lambda_{1}
$$

## Power Iteration

## any

Start with an initial gguess $\mathbf{q}_{0}$, and then iterate:
(1) Compute matrix-vector product and normalize it:

$$
\mathbf{q}_{k}=\frac{\mathbf{A} \mathbf{q}_{k-1}}{\left\|\mathbf{A} \mathbf{q}_{k-1}\right\|}
$$

(2) Use Raleigh quotient to obtain eigenvalue estimate:

$$
\hat{\lambda}_{k}=\mathbf{q}_{k}^{\star} \stackrel{A \mathbf{q}_{k}}{=} \rightarrow \text { altron }
$$

(3) Test for convergence: Evaluate the residual

$A q_{k} \approx \lambda_{k} q_{k}$

$$
\mathbf{r}_{k}=\mathbf{A} \mathbf{q}_{k}-\hat{\lambda}_{k} \mathbf{q}_{k}
$$

and terminate if the error estimate is small enough:

$$
\left|\lambda_{1}-\hat{\lambda}_{k}\right|<\varepsilon
$$

## Eigenvalues in MATLAB

- The Schur decomposition is provided by $[U, T]=\operatorname{schur}(A)$.
- In MATLAB, sophisticated variants of the QR algorithm (LAPACK library) are implemented in the function eig:

$$
\begin{gathered}
\Lambda=\operatorname{eig}(A) \\
{[X, \Lambda]=\operatorname{eig}(A)}
\end{gathered}
$$

- For large or sparse matrices, iterative methods based on the Arnoldi iteration (ARPACK library), can be used to obtain a few of the largest eigenvalues:

$$
\begin{gathered}
\Lambda=\operatorname{eigs}\left(A, n_{e i g s}\right) \\
{[X, \Lambda]=\operatorname{eigs}\left(A, n_{e i g s}\right)}
\end{gathered}
$$

## Outline

(1) Review of Linear Algebra
(2) Eigenvalue Problems
(3) Singular Value Decomposition
4. Principal Component Analysis (PCA)
(5) Conclusions

## Sensitivity (conditioning) of the SVD

$$
\mathbf{A}=\mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^{\star}
$$

- Since unitary matrices have unit 2-norm,

$$
\|\delta \Sigma\|_{2} \approx\|\delta A\|_{2}
$$

- The SVD computation is always perfectly well-conditioned!
- However, this refers to absolute errors: The relative error of small singular values will be large.
- The power of the SVD lies in the fact that it always exists and can be computed stably...but it is somewhat expensive to compute.

## Computing the SVD

- The SVD can be computed by performing an eigenvalue computation for the normal matrix $\mathbf{A}^{\star} \mathbf{A}$ (a positive-semidefinite matrix).
- This squares the condition number for small singular values and is not numerically-stable.
- Instead, modern algorithms use an algorithm based on computing eigenvalues / eigenvectors using the $Q R$ factorization.
- The cost of the calculation is $\sim O\left(m n^{2}\right)$, of the same order as eigenvalue calculation if $m \sim n$.

## Reduced SVD

The full (standard) SVD
$m \rightarrow 7 m$

$$
n \gg m
$$

$$
\begin{aligned}
\mathbf{A} & =\mathbf{U} \mathbf{\Sigma} \mathbf{V}^{\star}=\sum_{i=1}^{p} \sigma_{i} \mathbf{u}_{i} \mathbf{v}_{i}^{\star} \\
{[m \times n] } & =[m \times m][m \times n][n \times n],
\end{aligned}
$$

is in practice often computed in reduced (economy) SVD form, where $\boldsymbol{\Sigma}$ is $[p \times p]$ :

$$
\begin{aligned}
& {[m \times n]=[m \times n]\left[\underline{n \times n]}[n \times n] \quad \text { for } \quad \frac{m>n}{n}\right.} \\
& {[m \times n]=[m \times m][\underline{\underline{m \times m}]}[m \times n] \quad \text { for } \quad \underline{n>m}}
\end{aligned}
$$

This contains all the information as the full SVD but can be cheaper to compute if $m \gg n$ or $m \ll n$.

## In MATLAB

- $[U, \Sigma, V]=\operatorname{svd}(A)$ for full SVD, computed using a QR-like method.
- $[U, \Sigma, V]=\operatorname{svd}\left(A,{ }^{\prime}\right.$ econ') for economy SVD.
- The least-squares solution for square, overdetermined, underdetermined, or even rank-defficient systems can be computed using svd or pinv (pseudo-inverse, see homework).
- The $q$ largest singular values and corresponding approximation can be computed efficiently for sparse matrices using

$$
[U, \Sigma, V]=\operatorname{svds}(A, q)
$$

## Outline

(1) Review of Linear Algebra
(2) Eigenvalue Problems
(3) Singular Value Decomposition

4 Principal Component Analysis (PCA)
(5) Conclusions

## Low-rank approximations

- The SVD is a decomposition into rank-1 outer product matrices:

$$
\mathbf{A}=\mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^{\star}=\sum_{i=1}^{(r} \underset{i}{\sigma_{i} \mathbf{u}_{i} \mathbf{v}_{i}^{\star}}=\sum_{i=1}^{\text {unit vecter }} \mathbf{A}_{i}
$$

- The rank- 1 components $\mathbf{A}_{i}$ are called principal components, the most important ones corresponding to the larger $\sigma_{i}$.
- Ignoring all singular values/vectors except the first $q$, we get a low-rank approximation:

$$
\mathbf{A} \approx \hat{\mathbf{A}}_{q}=\mathbf{U}_{q} \boldsymbol{\Sigma}_{q} \mathbf{V}_{q}^{\star}=\sum_{i=1}^{q<T} \sigma_{i} \mathbf{u}_{i} \mathbf{v}_{i}^{\star}
$$

- Theorem: This is the best approximation of rank- $q$ in the Euclidian and Frobenius norm:

$$
\left\|\mathbf{A}-\hat{\mathbf{A}}_{q}\right\|_{2}=\sigma_{q+1}
$$

## Applications of SVD/PCA

- Statistical analysis (e.g., DNA microarray analysis, clustering).
- Data compression (e.g., image compression, explained next).
- Feature extraction, e.g., face or character recognition (see Eigenfaces on Wikipedia).
- Latent semantic indexing for context-sensitive searching (see Wikipedia).
- Noise reduction (e.g., weather prediction).
- One example concerning language analysis given in homework.

## Image Compression

$\gg A=r g b 2 g r a y(i m r e a d(' b a s k e t . j p g ')) ;$
$\gg$ imshow (A);
$\gg[U, S, V]=\operatorname{svd}($ double (A)) ;
$\gg$ $q=25$; \% Rank-r approximation
$\gg \operatorname{Acomp}=\mathrm{U}(:, \underline{1: q}) * \mathrm{~S}(1: q, 1: q) *(\mathrm{~V}(:, 1: q))^{\prime} ;$

## Compressing an image of a basket

We used only 25 out of the $\sim 400$ singular values to construct a rank 25 approximation:

## Principal Component Analysis

- Principal Component Analysis (PCA) is a term used for low-rank approximations in statistical analysis of data.
- Consider having $m$ empirical data points or observations (e.g., daily reports) of $n$ variables (e.g., stock prices), and put them in a data matrix $\mathbf{A}=[m \times n]$.
- Assume that each of the variables has zero mean, that is, the empirical mean has been subtracted out.
- It is also useful to choose the units of each variable (normalization) so that the variance is unity.
- We would like to find an orthogonal transformation of the original variables that accounts for as much of the variability of the data as possible.
- Specifically, the first principal component is the direction along which the variance of the data is largest.

## PCA and Variance

## PCA and SVD

- The covariance matrix of the data tells how correlated different pairs of variables are:

$$
\mathbf{C}=\mathbf{A}^{T} \mathbf{A}=[n \times n]
$$

- The largest eigenvalue of $\mathbf{C}$ is the direction (line) that minimizes the sum of squares of the distances from the points to the line, or equivalently, maximizes the variance of the data projected onto that line.
- The SVD of the data matrix is $\mathbf{A}=\mathbf{U} \boldsymbol{\Sigma} \mathbf{V}^{\star}$.
- The eigenvectors of $\mathbf{C}$ are in fact the columns of $\mathbf{V}$, and the eigenvalues of $\mathbf{C}$ are the squares of the singular values,

$$
\mathbf{C}=\mathbf{A}^{T} \mathbf{A}=\mathbf{V} \boldsymbol{\Sigma}\left(\mathbf{U}^{\star} \mathbf{U}\right) \boldsymbol{\Sigma} \mathbf{V}^{\star}=\mathbf{V} \boldsymbol{\Sigma}^{2} \mathbf{V}^{\star}
$$

Note: the eigenvalues values are necessarily real and positive since $\mathbf{C}$ is positive semi-definite.

Principal Component Analysis (PCA)

## Dimensionality reduction via PCA

original data space

Principal Component Analysis (PCA)

(5) Conclusions

## Summary for Eigenvalues

- Eigenvalues are well-conditioned for unitarily diagonalizable matrices (includes Hermitian matrices), but ill-conditioned for nearly non-diagonalizable matrices.
- Eigenvectors are well-conditioned only when eigenvalues are well-separated.
- Eigenvalue algorithms are always iterative.
- Estimating all eigenvalues and/or eigenvectors can be done by using iterative $Q R$ factorizations, with cost $O\left(n^{3}\right)$.
- Iterative algorithms are used to obtain only a few eigenvalues/vectors for sparse matrices.

- MATLAB has high-quality implementations of sophisticated variants of these algorithms.

## Summary for SVD

- The singular value decomposition (SVD) is an alternative to the eigenvalue decomposition that is better for rank-defficient and ill-conditioned matrices in general.
- Computing the SVD is always numerically stable for any matrix, but is typically more expensive than other decompositions.
- The SVD can be used to compute low-rank approximations to a matrix via the principal component analysis (PCA).
- PCA has many practical applications and usually large sparse matrices appear.
